

## Groundwater in Haddat Al Sham-Al Bayada Area, Western Saudi Arabia

M. Tahir Hussein and A.S. Bazuhair

*Faculty of Earth Sciences, King Abdulaziz University,  
P.O. Box 1744 - Jeddah 21441, Saudi Arabia*

**ABSTRACT.** Haddat Al Sham - Al Bayada area is situated about 100 km to the east-northeast of Jeddah. The average annual rainfall within the study area is about 100 mm. Groundwater occurs within the alluvial deposits of the wadi system and also within the clastic members of Cretaceous - Tertiary sedimentary succession. The alluvial aquifer is characterized by a hydraulic gradient of  $1.6 \times 10^{-2} - 8.8 \times 10^{-2}$ , an average transmissivity of 390 m<sup>2</sup>/day, average permeability of 34 m/day and a storage coefficient of  $1.12 \times 10^{-3} - 1.28 \times 10^{-1}$ . The groundwater within the clastic members moves under a hydraulic gradient of  $6.0 \times 10^{-4} - 1.4 \times 10^{-2}$ , an average transmissivity of 180 m<sup>2</sup>/day, and an average permeability of 10 m/day. Its storage coefficient is about  $5.4 \times 10^{-2} - 1.1 \times 10^{-3}$ .

Groundwater chemical composition and ionic relationships are as well discussed in this paper. Each of the aquifers is characterized by its own water quality.

The study area lies in proximity to the Arabian coast of the Red Sea. It is situated some 100 km to the east-northeast of Jeddah between latitudes 21° 30'N and 22° 00'N, longitudes 39° 20'E and 39° 45'E (Fig. 1). From east to west it includes Haddat Al Sham, Wadi Madsus, Al Bayada and Al-Shamiyah. The average depth of rainfall, is about 100 mm year<sup>-1</sup>. Rainfall occurs mainly in winter (December-January). Spring rains occur on the highlands during April.

The main rock units building up the area are (Table 1):

- Pre-Cambrian Cambrian Basement Complex,
- Cretaceous Haddat Al Sham Formation,
- Upper Cretaceous - Tertiary Usfan and Shumaysi Formations,

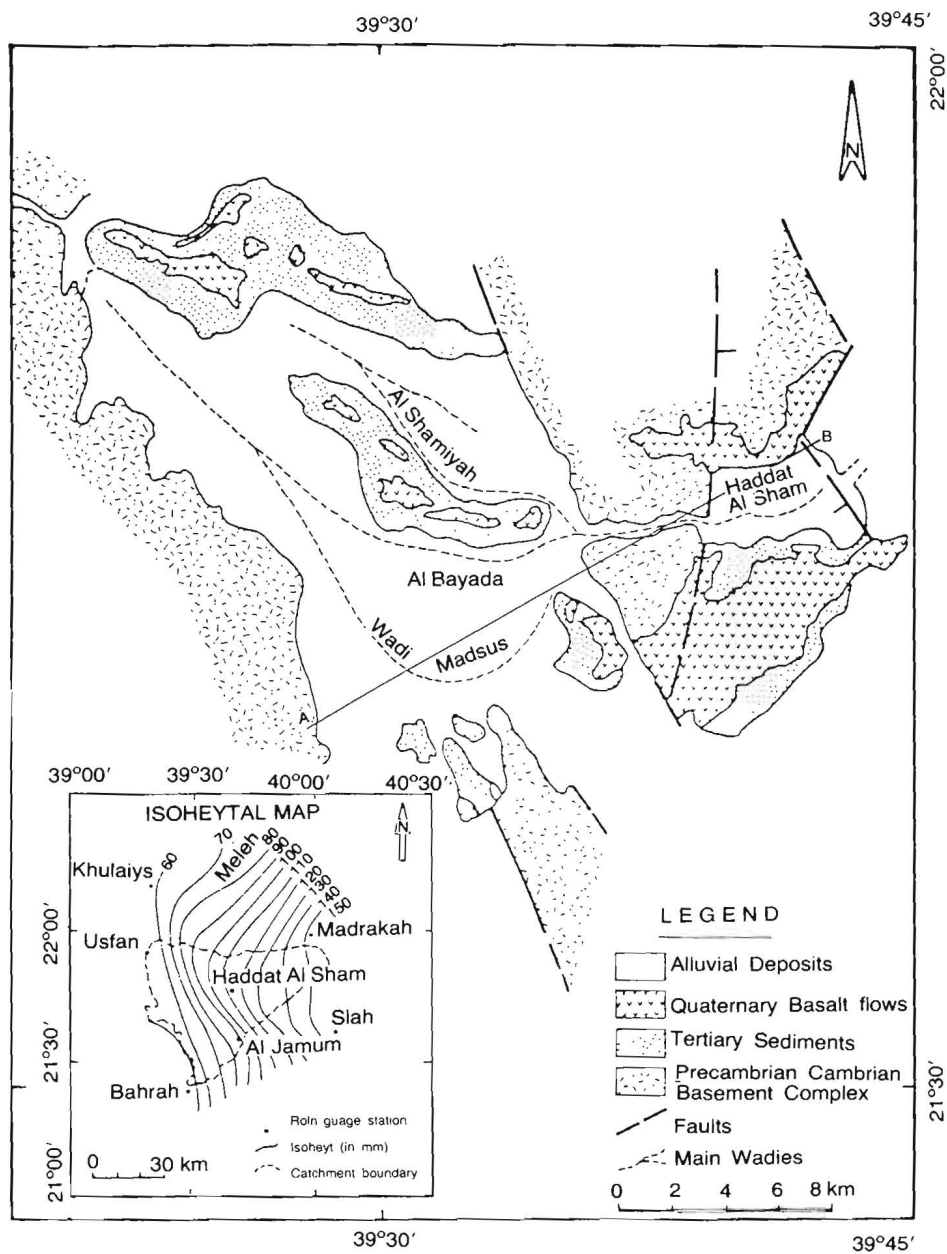

Fig. 1. Location map of the study area with an Isoheytal map including the surrounding areas

- Quaternary basalt flows,
- Alluvial Deposits.

The Basement includes a complex assemblage of igneous and metamorphic rocks intruded by basic, aplitic and pegmatitic dykes. Haddat Al Sham Formation consists mainly of varied sized sandstones, conglomerates and claystone (Bahafzalla *et al.* 1983). It rests unconformably on the Basement Complex. Usfan Formation consists mainly of sandstones, shales, marls and fossiliferous carbonate wedges (Karpoff 1955). In Haddat Al Sham area it overlies Haddat Al Sham Formation, elsewhere, and where it is found, it rests unconformably on the Basement rocks. Shumaysi Formation is composed of sandstones, siltstones and oolitic ironstone bands (Al Shanti 1966). It lies conformably on Usfan Formation. In Al Bayada area, Shumaysi Formation lies unconformably on the Basement Complex. The basalt flows form non-continuous caps overlying the upper levels of the previous rock units. Alluvial deposits form a heterogeneous assemblage of gravels, sand, silt and clayey silt.

From Cambrian through Quaternary the area had been subjected to different tectonic activities. These activities were accentuated with the opening of the Red Sea (Oligocene-Eocene). The prominent structural features in the area are

**Table 1.** Geological succession of Haddat Al Sham area (after Bahafzalla *et al.* 1983)

Age	Formation	Lithology	Thickness (m)
Quaternary - Recent	Surficial deposits including Alluvial deposits of the wadi system	heterogeneous assemblage of gravels, sands, silt and clay	≤ 30
Tertiary - Quaternary	Basalt flows	basalts and andesite	≤ 60
Eocene - Oligocenc	Shumaysi Formation	sandstone, siltstone with oolitic ironstone bands	20-200
Maestrichtian -	Usfan Formation	sandstone, shales, marls and carbonate ledge	
Crcaceous	Haddat Al Sham Formation	conglomerate, sandstone, breccia with claystone and siltstone	250
Cambrian-Precambrian	Basement Complex	Igneous and metamorphic complexes	

faulting and jointing. NE-SW faults form elongate grabens and horsts in the area (Basahel *et al.* 1983). Fig. 2 is a conceptual cross-section simplifying the geological succession in the area.

### Groundwater Occurrence and Movement

The groundwater occurs in the area within two geological units: the alluvial deposits of the wadi system and the clastic coarse members of the Cretaceous - Tertiary sedimentary succession (Fig. 3).

Within the wadis groundwater occurs in the heterogenous assemblage of gravels, sand, silt and clay that make the wadi-fill deposits. The depth to the water level in the wadi-fill deposits varies between 7 metres in the upstream areas (Haddat Al-Sham) to some 13 metres in the downstream areas. This depth fluctuates according to the time of the year and recharge conditions wherever available. The general groundwater flow within the wadi system follows the surface drainage *i.e.* from the upstream to the downstream of the wadis. A lateral component of flow occurs as we go away from the main channel of the wadi and this lateral component might contribute towards the recharge of the sedimentary units below. Fig. 4 explains this situation explicitly. The water-level ranges from 90 m to 230 m above mean sea level and the hydraulic gradient varies between  $1.6 \times 10^{-2}$  and  $8.8 \times 10^{-3}$ . The transmissivity in the wadi-fill ranges between  $72 \text{ m}^2/\text{day}$  and  $713 \text{ m}^2/\text{day}$ , the storage coefficient varies from  $1.28 \times 10^{-1}$  to  $1.12 \times 10^{-3}$  (Table 2). Local semi-confined conditions are present due to facies changes and local abundance of clay lenses within the wadi-fill deposits. The hydraulic permeability of the wadi-fill deposits measured in the lab. reveals a range of 5.6 - 62.6 m/day.

Groundwater occurs as well within the clastic members of the sedimentary succession in the study area. A number of wells have penetrated the wadi-fill deposits and the upper clays of the Shumaysi Formation and tapped groundwater from the clastic coarse member in Haddat Al Sham area, Al Bayada, Al Shamiyah and in the vicinity of wadi Madsus. Groundwater has been struck in these areas at depths between 23, 25, 33 metres respectively. Water has risen above these depths for some 2-5 metres above the confining clay member. Groundwater occurring in the upper members of the sedimentary succession is largely controlled by a complexity of geological elements including the block faulting mechanism that effects the sedimentary succession and the lithological facies variations. Thus a complicated picture for the underground flow exists (Fig. 5). The situation needs more understanding of the geometries of the water-bearing horizons and this

 10, 11, 15, 16 are tapping semiconfined aquifer  
 4, 12, 13, 14 are tapping confined aquifer

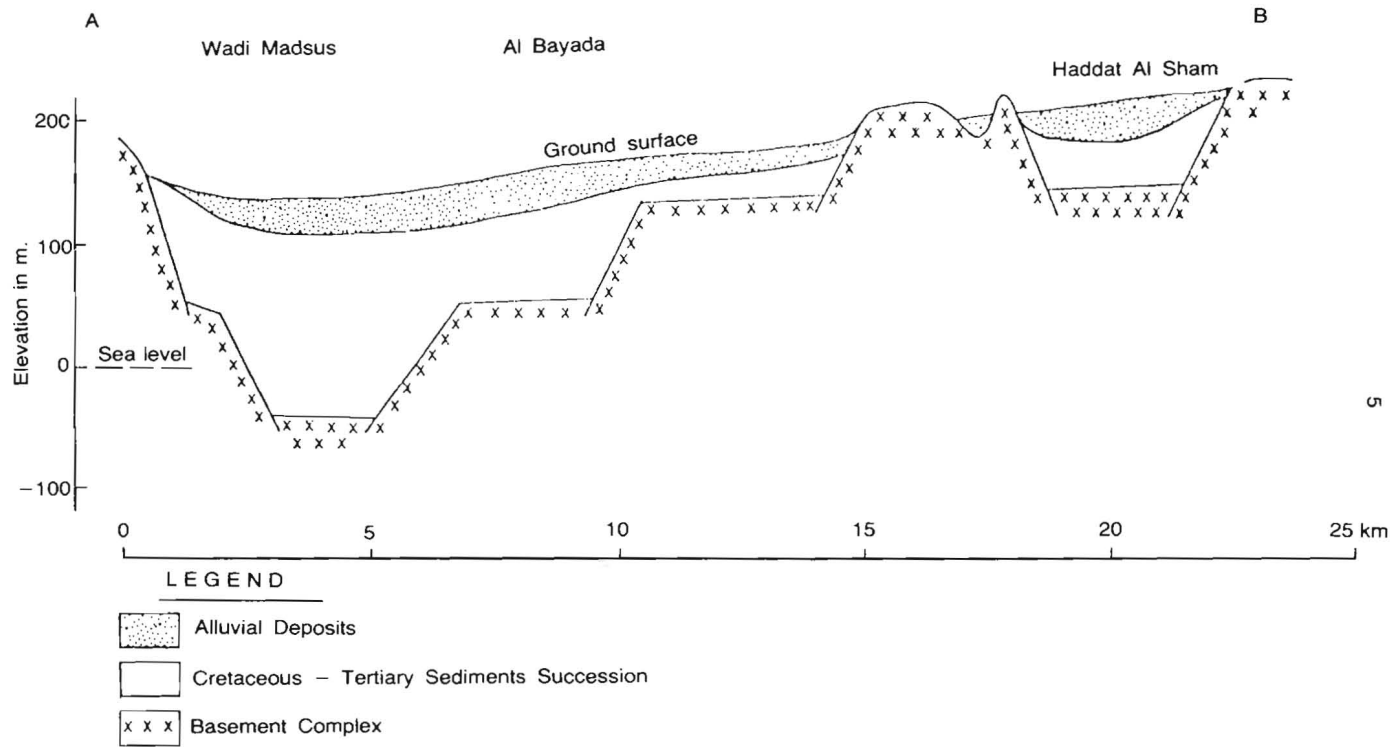

Fig. 2. Generalized geological cross-section (Basement complex configuration is based on DGMR 1966).

needs detailed gravity and resistivity surveys in the area. The average hydraulic gradient for this case is ranging between  $1.4 \times 10^{-2}$  and  $6.0 \times 10^{-4}$  (Fig. 5). The transmissivity values obtained are between  $51 \text{ m}^2/\text{day}$  and  $316 \text{ m}^2/\text{day}$  (Fig. 6). The storage coefficient ranges from  $5.4 \times 10^{-4}$  to  $1.12 \times 10^{-3}$ . Some values of the storage coefficient reflect semi-confined conditions which can be explained as follows: in some areas the upper clayey member might be reduced, eroded or it could be silty in nature or that this aquifer is hydraulically inter-connected with the upper unconfined wadi-fill aquifer. Laboratory measurements on the hydraulic conductivity gave average values between 3.7 and 156 m/day (Table 2). Recent recharge to this lower aquifer is limited to outcrop areas and in places where there is interconnection with the upper unconfined alluvial deposits of the wadis (Fig. 4).

### Groundwater Quality

102 water samples were collected from the study area to shed light on the groundwater chemical composition of the two aquifers. Table 3 summarizes the analytical methods used in this study. Table 4 includes the results of the chemical analysis. The groundwater of the confined aquifer is generally characterized with higher electrical conductivity values (2760 to 13400 micromhos/cm) while those of the unconfined aquifer have relatively lower electrical resistivity values (679 to 7920 micromhos/cm) *i.e.* the total mineralization of the groundwater tapped from the clastic members of the sedimentary succession is relatively higher than that of the groundwater tapping the wadi-fill deposits. The relative ionic concentrations in the confined aquifer are generally as follows:

When the confined aquifer is interconnected with upper unconfined aquifer of the wadi-fill deposits exceptions to the above mentioned generalization may occur. The relative cationic concentrations in the unconfined aquifer are as follows:

The anionic concentrations are:

$\text{HCO}_3^{--} > \text{Cl}^- > \text{SO}_4^{--}$  in the upstream of Haddat Al Sham, while in the other sub-areas anionic concentrations are:  $\text{Cl}^- > \text{SO}_4^{--} > \text{HCO}_3^{--}$

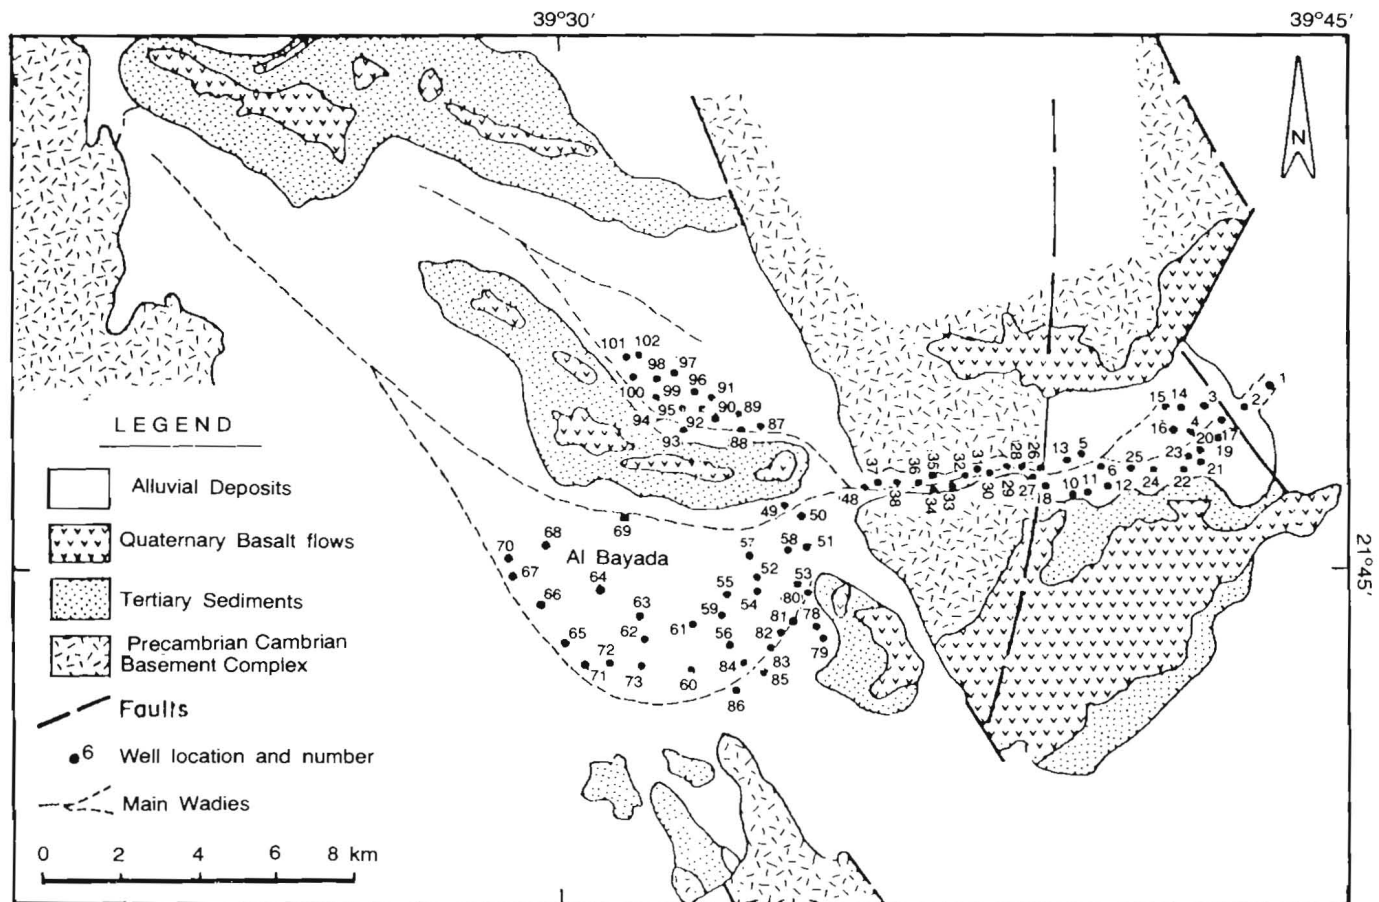

Fig. 3. Well-location map.

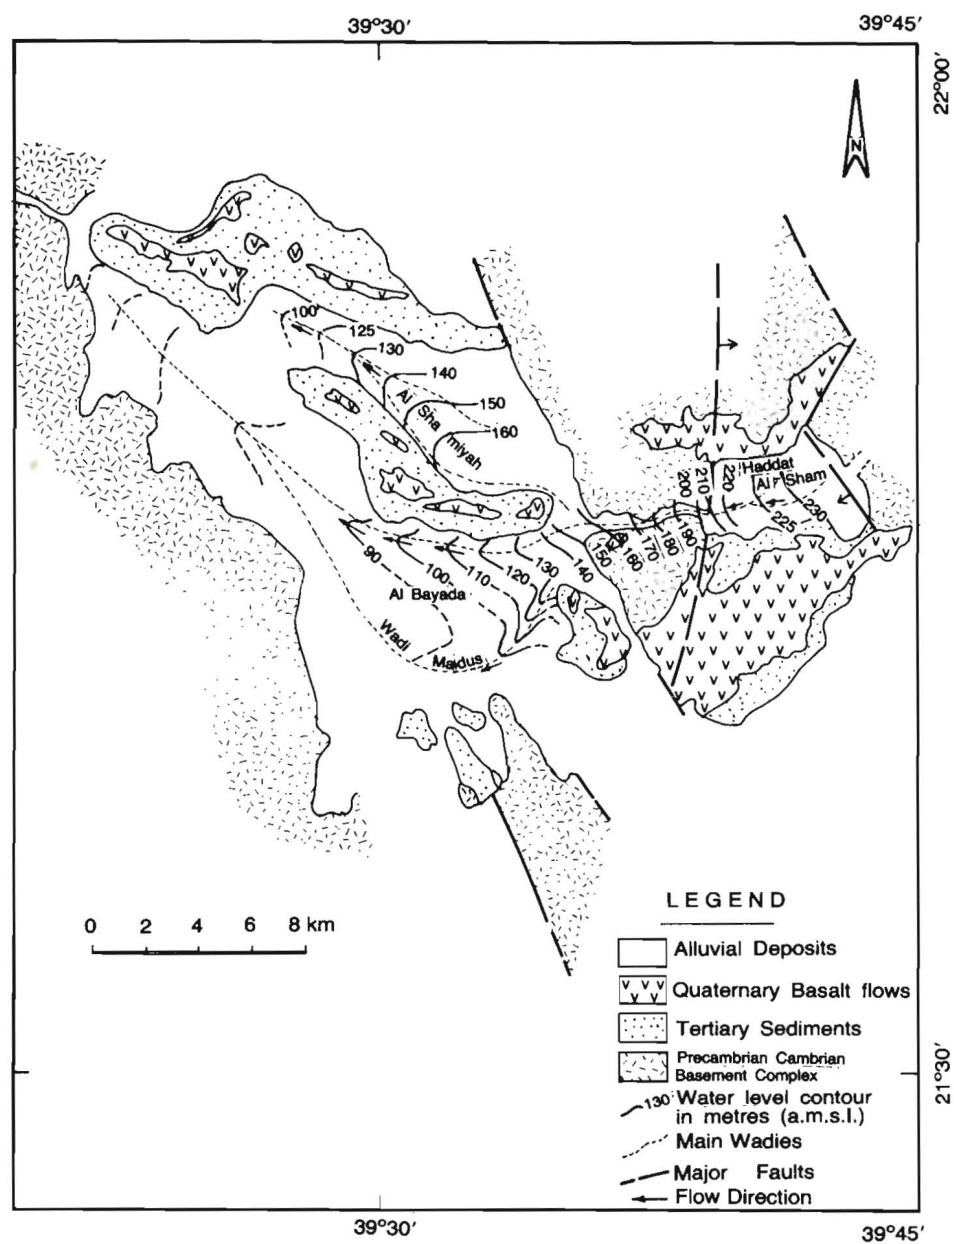

Fig. 4. Water-table map for the alluvial aquifer in Haddat Al Sham - Al Bayada area.

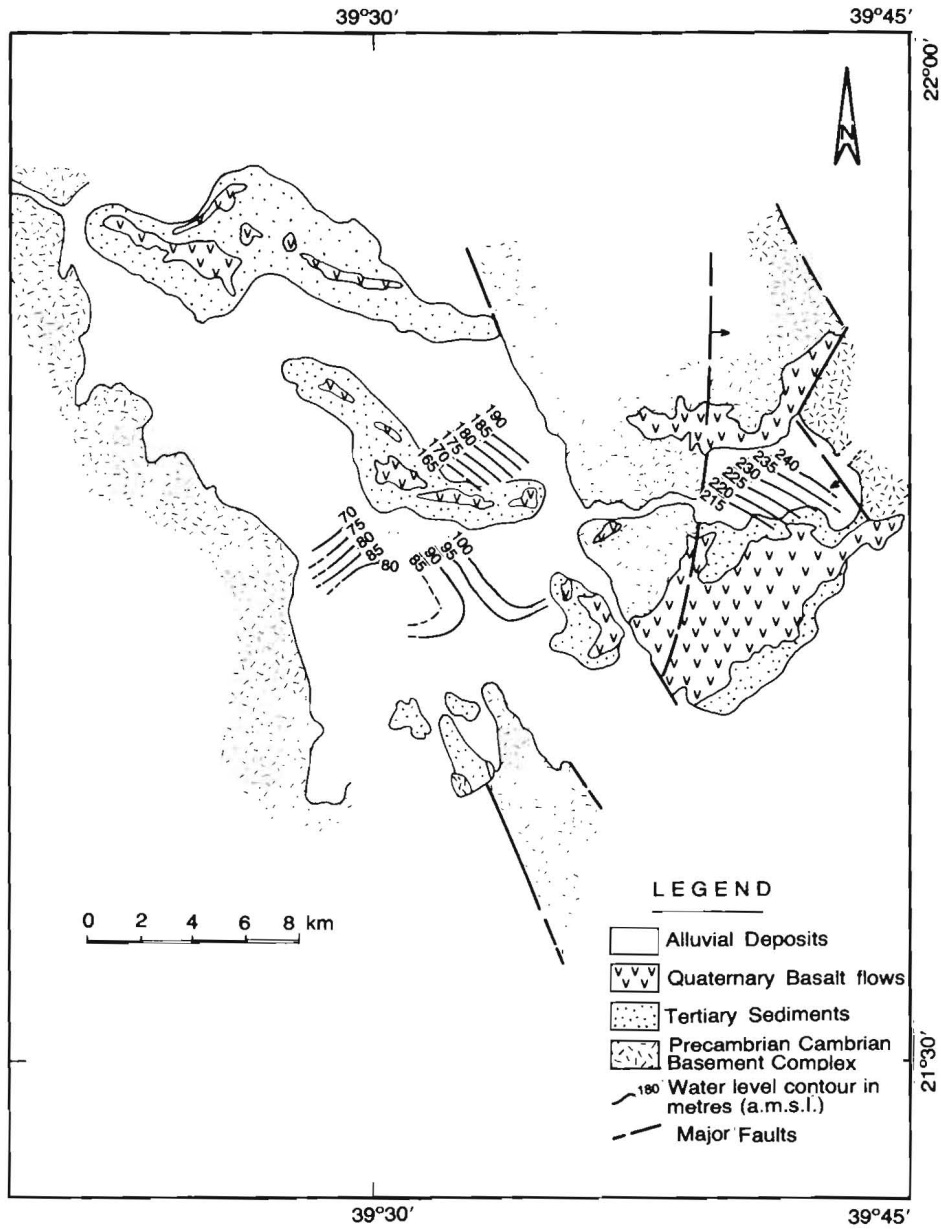

Fig. 5. Piezometric surface map for the confined aquifer in the study area.

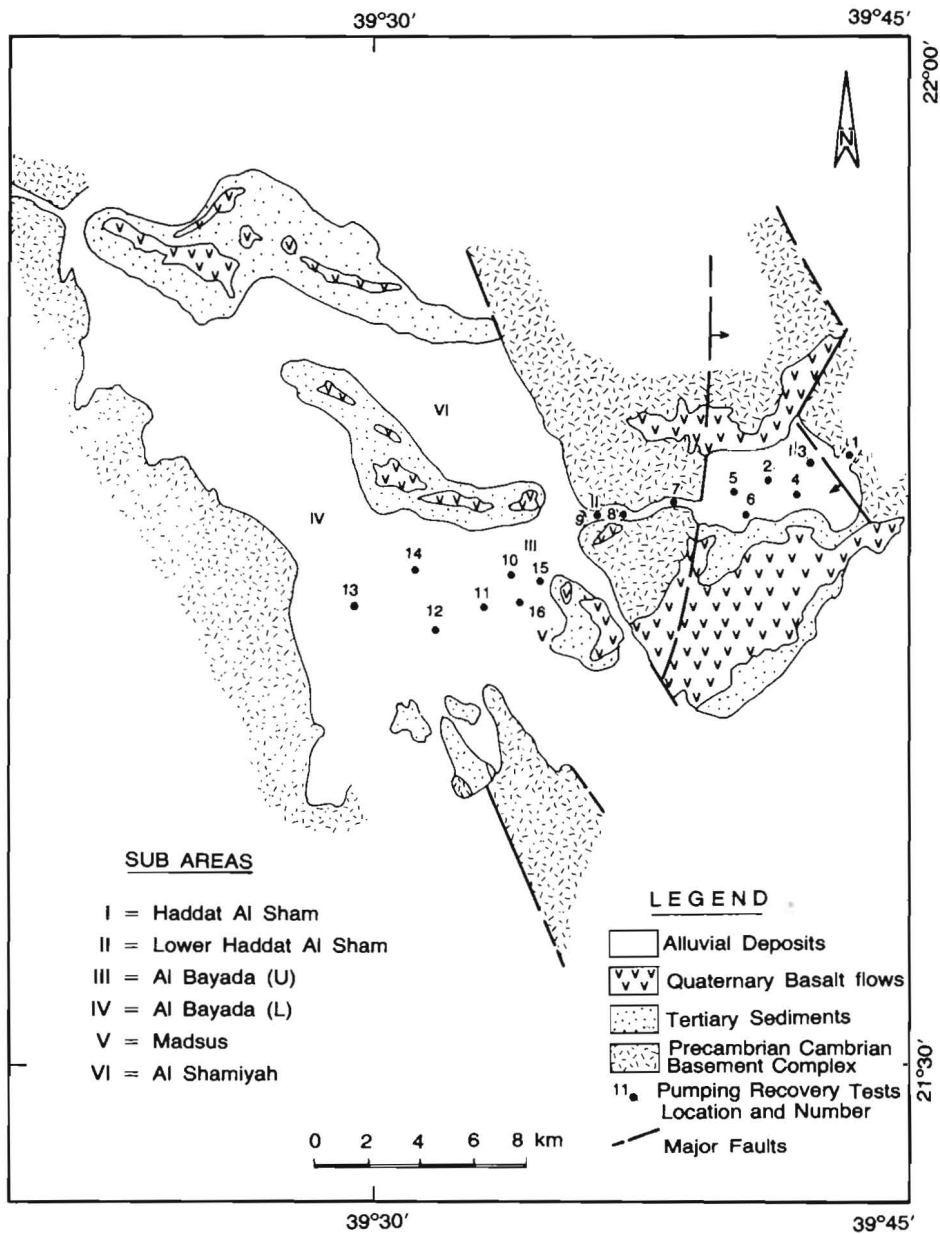

Fig. 6. Locations of Pumping and Recovery Tests.

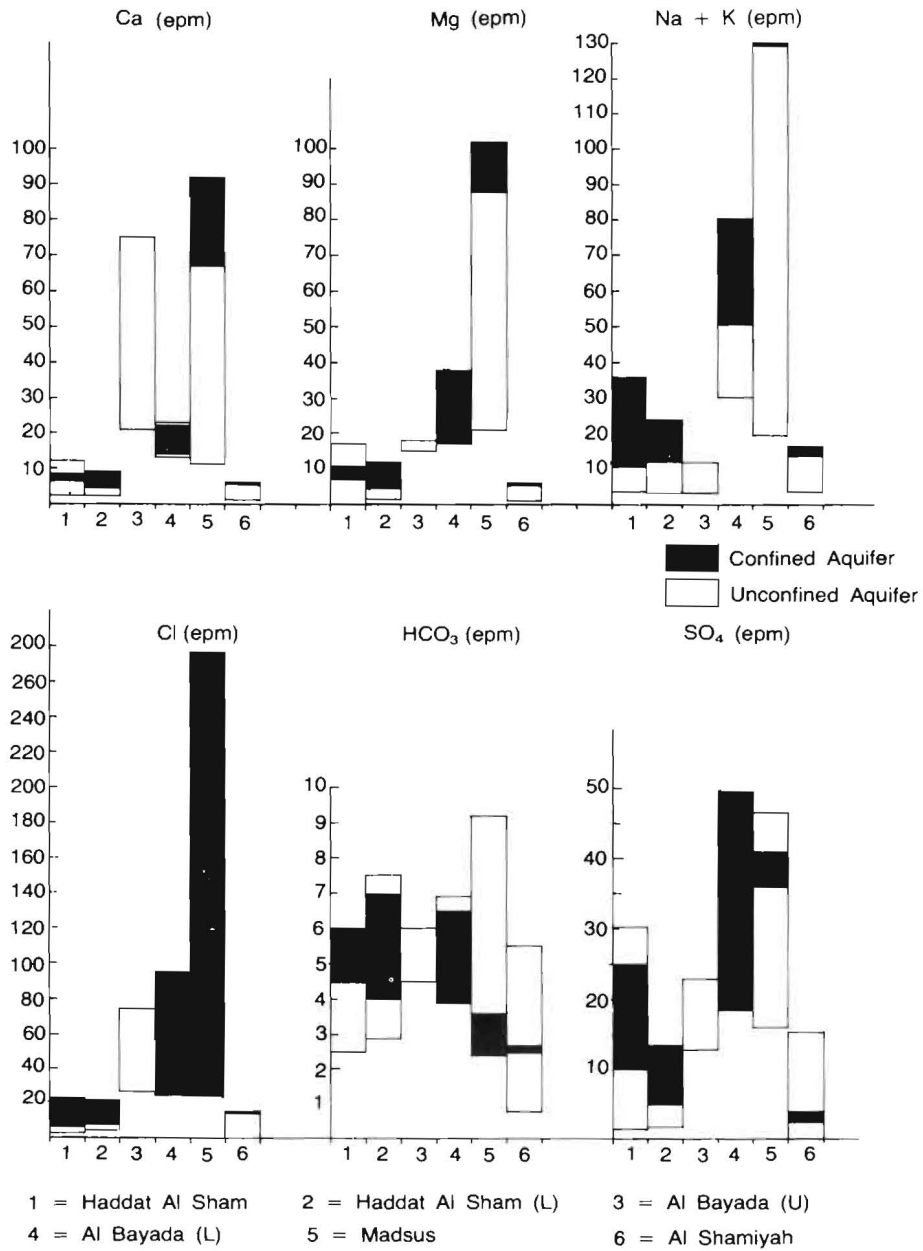

Fig. 7. Ionic concentration for the different sub-areas.

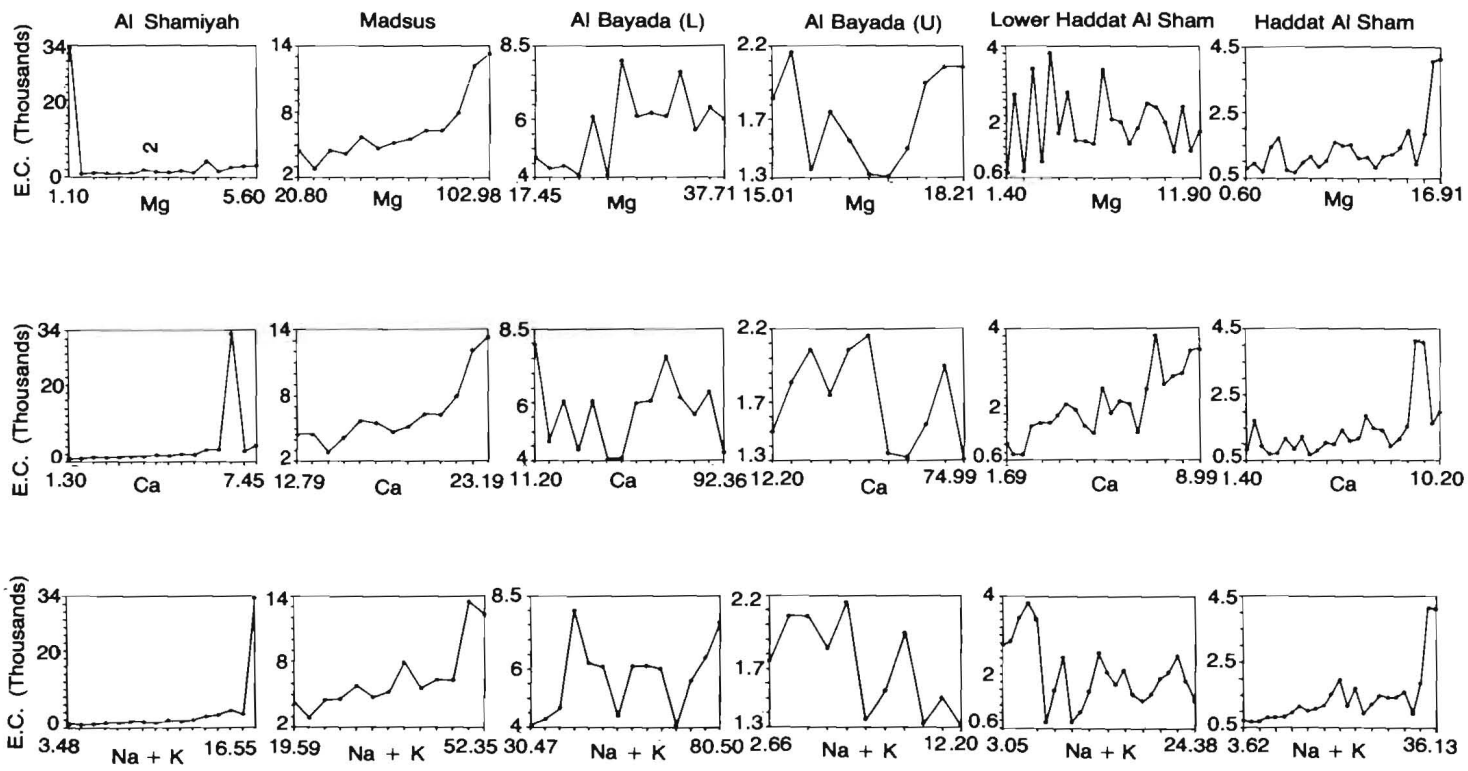

Fig. 8. Electrical Conductivity/cation relationships. (E.C. in micromhos/cm, cations conc. in epm)

In dealing with individual ion concentration for the different sub-areas (Fig. 7) it is difficult to visualize a certain pattern.

The relationship of each ion concentration with the electrical conductivity is shown in figures 8 and 9. In the upstream area, Haddat Al Sham, the relationship is direct while in lower Haddat Al Sham and Al Bayada sodium has been substituted by calcium and to a lower extent by magnesium. In these areas the relationship of the electrical conductivity with the chloride and sodium has become indirect; with the sulphate and calcium the electrical conductivity is directly related *i.e.* the soil is getting more colloidal. In Al Shamiyah the relationships resemble those of the upstream in Haddat Al Sham. From our field observations the intermediate sector of Al-Bayada is lying within a plain where evaporites are available. However, the bicarbonate concentration did not show any effect and its values remained nearly constant. This can be explained that it formed the media of the reaction.

It can thus be concluded that the water quality of each well shown in Table 4 depends on the penetration through the aquifer.

### Conclusions

Groundwater occurs in Haddat Al Sham - Al Bayada area within two water-bearing horizons: an upper unconfined aquifer formed mainly of alluvial deposits of the wadi system in the area, and a lower confined aquifer formed by

\* confined aquifer

\*\* semi-confined aquifer

the clastic members of the Cretaceous - Tertiary sedimentary succession. The alluvial deposits are characterized with an average permeability of 34 m/day, an average transmissivity of 390 m<sup>2</sup>/day and an average storage coefficient of  $6.5 \times 10^{-2}$ . The confined aquifer is characterized by an average permeability of 10 m/day, and average transmissivity of 180 m<sup>2</sup>/day and an average storage coefficient of  $8.3 \times 10^{-4}$ .

Electrical conductivity within the unconfined aquifer ranges from 679 to 7920 micromhos/cm while in the confined aquifer it ranges from 2760 to 13400 micromhos/cm. The ionic composition of each of the two aquifers is generally distinguished.

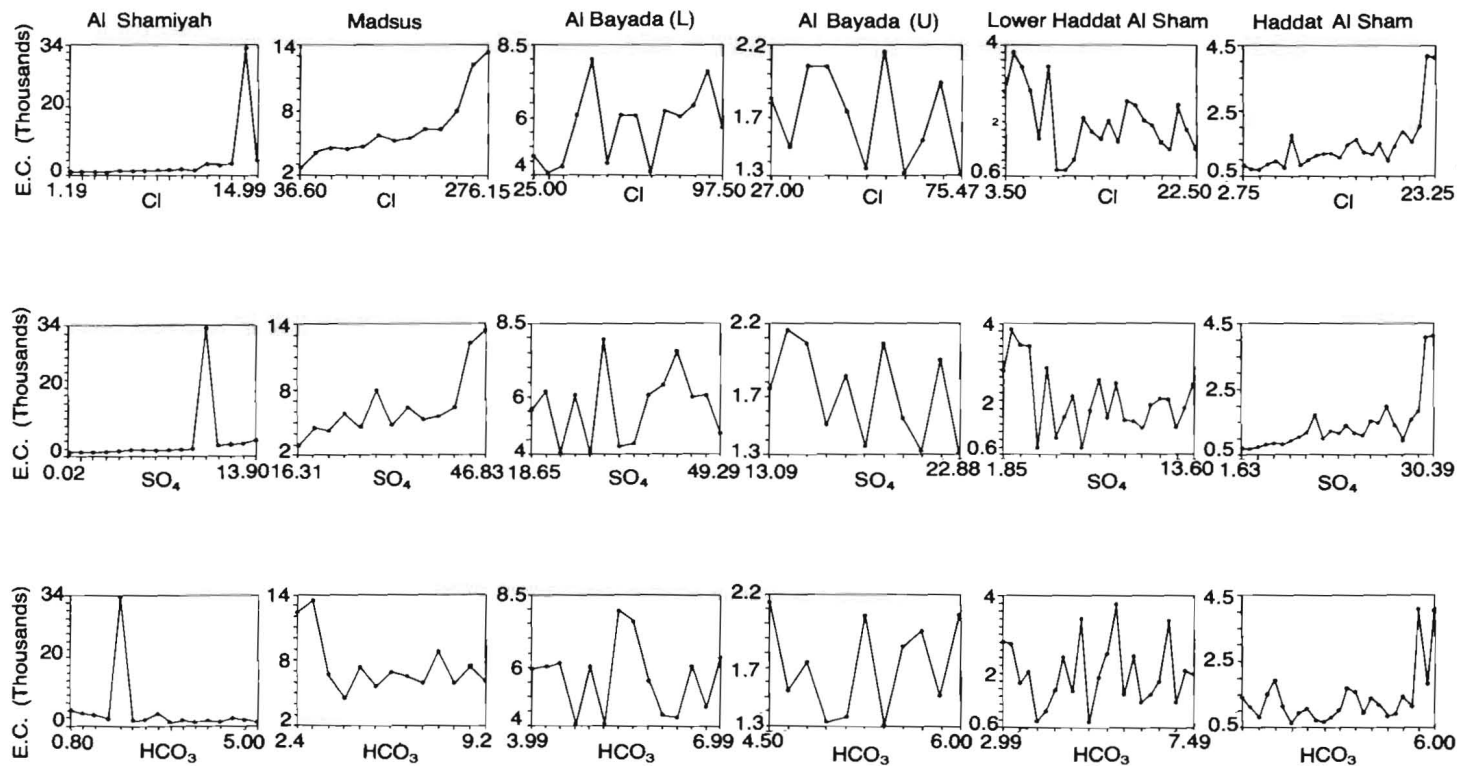

Fig. 9. Electrical Conductivity/anions relationships. (E.C. in icromhos/cm, anions conc. in epm).

## المياه الجوفية في منطقة هدى الشام - البياضة غرب المملكة العربية السعودية

محمد طاهر حسين و عبدالغفار سعيد بازهير

كلية علوم الأرض - جامعة الملك عبدالعزيز - ص. ب: ١٧٤٤ - جدة ٢١٤٤١  
المملكة العربية السعودية

تقع منطقة هدى الشام - البياضة على مسافة نحو ١٠٠ كم شرق - شمال شرق مدينة جدة. وتكتسب هذه المنطقة أهمية خاصة لتواجد المياه فيها إلى حد ما مقارنةً ببقية أجزاء الدرع العربي. ونتيجةً لهذه الظروف السائدة يتواجد عدد من المزارع الصغيرة للخضروات وعدد من مزارع تربية الحيوانات حيث تشكل هذه المزارع مصدراً محلياً مهماً للخضروات لمدينة جدة وضواحيها.

هدف هذا البحث هو دراسة المياه الجوفية في المنطقة من حيث تواجدها، حركتها، خواص الطبقات الحاملة لها، نوعيتها وعلاقات الأيونات الرئيسية المذابة فيها.

يبلغ متوسط هطول الامطار في منطقة هدى الشام - البياضة حوالي ١٠٠ ملم / سنة. تتواجد المياه الجوفية في طبقتين حاملتين للمياه هما:

- ١ - طبقة الرواسب الوديانية والتي تشكل خزاناً حراً غير محصور في مجمله.
- ٢ - طبقة الصخور الرسوبية الحتاتية التي تتبع للعصر الكريتاسي الثلاثي في خزان محصور.

تتميز طبقة الرواسب الوديانية بميل هيدروليكي يتراوح بين  $1,6 \times 10^{-2}$  إلى  $8,8 \times 10^{-2}$ ، متوسط إنتقالية يبلغ  $390 \text{ م}^2 / \text{يوم}$ ، ومتوسط نفاذية يبلغ  $34 \text{ م} / \text{يوم}$  ومعامل تخزين يتراوح بين  $1,12 \times 10^{-3}$  إلى  $1,28 \times 10^{-1}$ . تتحرك المياه الجوفية الموجودة في طبقات الصخور الرسوبية تحت أثر ميل هيدروليكي يتراوح بين  $6,0 \times 10^{-4}$  إلى  $1,4 \times 10^{-2}$ ، متوسط إنتقالية يبلغ  $180 \text{ م}^2 / \text{يوم}$ ، متوسط نفاذية يبلغ  $10 \text{ م} / \text{يوم}$ . يتراوح معامل التخزين في هذا الخزان بين  $5,4 \times 10^{-2}$  إلى  $1,1 \times 10^{-3}$ .

كما يناقش هذا البحث المحتوى الكيميائي للمياه الجوفية في كل من الخزائين (الخزان الحر والخزان المحصور). وقد مثلت نتائج التحليل الكيميائية للعناصر الرئيسية على أشكال بيانية مختلفة ميزت المياه الموجودة في كل خزان على حدة من ناحيتي التركيب وكيمياء المياه كما بينت الخصائص الكيميائية العامة لأجزاء منطقة الدراسة المختلفة.
